(Dated: September 3, 2012)

The influence of bond randomness on long range magnetic ordering in the weakly coupled $S = 1/2$ antiferromagnetic spin chain materials $\text{Cu}(\text{py})_2(\text{Cl}_{1-x}\text{Br}_x)_2$ is studied by muon spin rotation and bulk measurements. Disorder is found to have a strong effect on the ordering temperature T_N , and an even stronger one on the saturation magnetization m_0 , but considerably more so in the effectively lower-dimensional Br-rich materials. The observed behavior is attributed to Random Singlet ground states of individual spin chains, but remains in contradiction with chain mean field theory [1] predictions. In this context, we discuss the possibility of a universal *distribution* of ordered moments in the weakly coupled Random Singlet chains model.

The ground states of unfrustrated classical systems are typically robust with respect to weak Hamiltonian disorder. A case in point is the classical Heisenberg antiferromagnet (HAF). Randomizing the strength (but not the signs) of exchange interactions leaves the fully aligned Neel ground state completely intact. In contrast, in quantum systems, arbitrarily weak disorder will modulate the strengths of local quantum fluctuation and often qualitatively reconstruct the ground state. The one-dimensional quantum $S = 1/2$ HAF is an extreme example. For uniform chains, the ground state is a Tomonaga-Luttinger spin liquid (TLSL) [2]. The introduction of arbitrary weak bond randomness gives rise to the so-called Random Singlet (RS) phase [3–6]. In the RS state, spin correlations are protected from localization effects by particle-hole symmetry [2, 7]. Nevertheless, the scaling laws [6, 8, 9], although universal and independent of the details of disorder, are markedly different from those of the TLSL. In experiments on real materials, one has to deal with quasi-one-dimensional (quasi-1D) spin systems. A divergent correlation length in individual chains ensures 3D long range order at $T_N > 0$ for arbitrary weak inter-chain interactions J' , in both the disorder-free [10] and disordered cases [1, 6]. An intriguing question is to what extent the peculiarities of the RS state in $d = 1$ translate into unusual features of the ordered phase in $d = 3$.

To date, RS-forming bond randomness in quasi-1D magnets has received considerably less attention than dilution-type disorder due to spin substitution [11–13]. For the former, the existing predictions are derived from chain-Mean Field (chain-MF) theory [1]. The main result is that random bonds tend to *increase* both T_N and the ordered moment m_0 at $T \rightarrow 0$. This effect is related to an abundance of very loosely coupled and almost free spins in the RS state of isolated chains [3, 5]. In coupled chains, for weak J' , one gets $T_N \propto J'm_0$. In contrast, for disorder-free case, the in-chain interactions enter the relation explicitly: $T_N \propto Jm_0^2$ [14]. On the experimental side, the challenge is to measure the very small sublattice mag-

netization that arise in the weak-coupling regime, where this theory may be expected to apply. In the present work we overcome this difficulty by employing the sensitive muon spin rotation (μSR) technique, which has emerged as a tool of choice for the study of quantum magnetism [15]. We directly measure the relative variations of m_0 and T_N in the prototypical bond-disordered quasi-1D $S = 1/2$ HAF systems $\text{Cu}(\text{py})_2(\text{Cl}_{1-x}\text{Br}_x)_2$. We find that both quantities are *reduced* by disorder and that m_0 is far more sensitive than the transition temperature, in apparent contradiction with chain-MF predictions.

Our target compounds are derivatives of $\text{Cu}(\text{py})_2\text{Cl}_2$, one of the first known and extensively studied $S = 1/2$ spin chain materials [16]. Single crystals samples with varying Br content x are straightforward to grow from solution by slow evaporation. In $\text{Cu}(\text{py})_2\text{Cl}_2$ (space group $P2_1/n$, $a = 16.967\text{\AA}$, $b = 8.5596\text{\AA}$, $c = 3.8479\text{\AA}$, $\beta = 91.98^\circ$) the chains are formed by magnetic $S = 1/2$ Cu^{2+} ions linked by superexchange bonds via the halogen sites. The temperature dependence of magnetic susceptibility (Fig. 1a) shows a broad Bonner-Fischer (BF) maximum [17, 18], characteristic of a quantum $S = 1/2$ chain with an AF exchange constant $J_{x=0} = 2.35$ meV. The chain-structure of $\text{Cu}(\text{py})_2\text{Br}_2$ is quite similar ($P2_1/n$, $a = 8.424\text{\AA}$, $b = 17.599\text{\AA}$, $c = 4.0504\text{\AA}$, $\beta = 97.12^\circ$ [19]), as are the measured magnetic susceptibility curves. However, the in-chain exchange constant is larger: $J_{x=1} = 4.58$ meV. Weak inter-chain interactions lead to 3D ordering in both materials, at $T_N = 1.15\text{K}$ K [20] and $T_N = 0.72$ K for $\text{Cu}(\text{py})_2\text{Cl}_2$ and $\text{Cu}(\text{py})_2\text{Br}_2$, respectively. The transitions are marked by well-defined lambda-anomalies in the measured temperature dependence of specific heat $C(T)$, as shown in Fig. 1b [33]. Knowing T_N and J , allows us to estimate the effective inter-chain coupling constants [21]: $J'_{x=0} = 0.05$ meV and $J'_{x=1} = 0.03$ meV for the two materials, correspondingly. The bromide is clearly a much more one-dimensional system. This is also evident from its much weaker lambda-anomaly. It is useful to estimate the ordered moment at $T \rightarrow 0$. Based on chain-MF results, for

FIG. 1: (Color online) Bulk properties of $\text{Cu}(\text{py})_2(\text{Cl}_{1-x}\text{Br}_x)_2$ samples. (a) Measured temperature dependence of magnetic susceptibility for a field applied along the chain axis (symbols), and fit of the theoretical curve for the uniform quantum $S = 1/2$ HAF chain [17, 18] (solid line). From the bottom up, the data are offset along the y axis by 0, 1, 2, 3, 4.2, and $5.8 \cdot 10^{-3}$ emu/mol, respectively. (b) Measured temperature dependence of specific heat (symbols). The vertical offsets are 0, 0.16, 0.27, 0.55, 0.75 and 1 J/mol K, respectively.

$\text{Cu}(\text{py})_2\text{Cl}_2$ and $\text{Cu}(\text{py})_2\text{Br}_2$ we get $m_{0,x=0} = 0.15 \mu_B$ and $m_{0,x=1} = 0.08 \mu_B$, respectively.

As determined by single crystal X-ray diffraction and chemical elemental analysis, the structures of $\text{Cu}(\text{py})_2\text{Cl}_2$ and $\text{Cu}(\text{py})_2\text{Br}_2$ are stable with respect to chemical substitution of Cl for Br and vice versa, for $x < 0.4$ and $x > 0.6$, respectively. Due to a difference in Cl and Br ionic radii, such disorder randomizes the Cu-halogen-Cu bond angles and thereby the magnitude of in-chain ex-

change interactions, whilst leaving the spins themselves unaffected. This strategy of creating bond-disordered systems has been previously successfully applied in other materials such as IPA- $\text{Cu}(\text{Cl}_{1-x}\text{Br}_x)_3$ [22], piperazinium- $\text{Cu}_2(\text{Cl}_{1-x}\text{Br}_x)_6$ [23], $\text{H}_8\text{C}_4\text{SO}_2\cdot\text{Cu}_2(\text{Cl}_{1-x}\text{Br}_x)_4$ [24] and $\text{NiCl}_2\cdot 4\text{SC}(\text{NH}_2)_2$ [25]. Due to the slightly different structures of the parent compounds, we are actually dealing with *two* tunable random-bond spin chain materials, on the Cl-rich and Br-rich ends of the $\text{Cu}(\text{py})_2(\text{Cl}_{1-x}\text{Br}_x)_2$ line, respectively. We will reserve the formula $\text{Cu}(\text{py})_2(\text{Cl}_{1-x}\text{Br}_x)_2$ for Cl-rich compounds ($x < 0.5$) and use $\text{Cu}(\text{py})_2(\text{Br}_{1-y}\text{Cl}_y)_2$ to denote materials on the Br end ($y < 0.5$).

The bulk properties of the halogen-disordered samples resemble those of the corresponding disorder-free systems. Typical measured magnetic susceptibility data are plotted symbols in Fig. 1. The derived average in-chain exchange constant J steadily increases with increasing Br content. A 3D magnetic ordering transition is observed at low temperatures in all composition studied (Fig. 1, lower panel). T_N decreases with Br content on the Cl-rich end and with Cl concentration in Br-rich samples (Fig. 2). The variation is more pronounced in $\text{Cu}(\text{py})_2(\text{Br}_{1-y}\text{Cl}_y)_2$. Moreover, the corresponding lambda-anomaly weakens and slightly broadens with increasing Cl content in $\text{Cu}(\text{py})_2(\text{Br}_{1-y}\text{Cl}_y)_2$, while it remains almost unchanged in $\text{Cu}(\text{py})_2(\text{Cl}_{1-x}\text{Br}_x)_2$. The measured transition temperature and average exchange constant are plotted versus composition in Fig. 2.

The main focus of the present study is on μ -SR measurements. This technique has been instrumental in the study of very small static [26, 27] and dynamic [28, 29] moments in spin chain systems. It probes the local magnetic fields at the stopping sites of muons implanted into the sample [30]. These, in turn, are expected to be propor-

FIG. 3: (Color online) Muon spin asymmetry measured vs. time in several $\text{Cu(py)}_2(\text{Cl}_{1-x}\text{Br}_x)_2$ and $\text{Cu(py)}_2(\text{Br}_{1-y}\text{Cl}_y)_2$ samples at $T \sim 20$ mK (solid symbols) and just above T_N (open symbols). The plots for $y = 0, 0.05$ and 0.1 and $x = 0.05, 0$ are offset along the y axis by $0, 0.1, 0.2, 0.3$ and 0.43 , respectively. The solid lines are fits to the data as described in the text.

tional to the static ordered moment. We performed measurements on powder samples of $\text{Cu(py)}_2(\text{Cl}_{1-x}\text{Br}_x)_2$ and $\text{Cu(py)}_2(\text{Br}_{1-y}\text{Cl}_y)_2$ with $x = 0, 0.05$ and $y = 0, 0.05$ and 0.1 at the LTF spectrometer at the $S\mu S$ muon source at Paul Scherrer Institut. Typical muon spin relaxation/rotation curves measured in zero applied field (ZF) are shown in Fig. 3. Several distinct time scales are apparent. In all samples, a very rapid decay at short times can be attributed to muonium formation with the organic ligand [31]. This contribution appears to be temperature-independent and is not directly relevant to the physics discussed here. At the largest time scales, a slowly decaying tail is due to the non-precessing muon spin components parallel to the local field, and to muons stopping outside the sample [30].

As expected, in the paramagnetic phases of all samples one only observes a slow decay of muon polarization, with no oscillatory behavior. Representative data collected at $T > T_N$ are shown in open symbols in Fig. 3. They can be modeled with exponential decay processes, as shown in dashed lines. We conclude that above the ordering transition, all materials studied behave very similarly, despite the different levels of disorder.

Clear differences emerge at low temperatures, in the magnetically ordered phase (Fig. 3, solid symbols). Although the relevant time scales turned out to be strongly dependent on composition, it is possible to provide a

FIG. 4: (Color online) Magnetic order parameter (characteristic field at the principal muon stopping site) plotted against temperature in units of the average in-chain exchange constant J in $\text{Cu(py)}_2(\text{Cl}_{1-x}\text{Br}_x)_2$ and $\text{Cu(py)}_2(\text{Br}_{1-y}\text{Cl}_y)_2$ (symbols). Within each family of materials, the relative magnitudes of the order parameter can be directly compared. Lines are guides to the eye.

common description of the low-temperature μ -SR spectra in all samples. In addition to the fast and slow background contributions described above, for $T < T_N$, the main effect is the appearance of spontaneous muon spin precession. An application of a small longitudinal field parallel to the muon spin direction recovered all polarization apart from the muonium contribution. This observation shows that the observed spin relaxation and rotation are due to *static* internal fields, which we attribute to ordered Cu^{2+} moments. We chose to model these processes as a sum of a damped Bessel function and an exponential term. The spectra are then described as:

$$A(t) = A_1 J_0(\omega t + \phi) \exp(-\lambda_1 t) + A_2 \exp(-\lambda_2 t) + A_{\text{fast}} \exp(-\lambda_{\text{fast}} t) + A_{\text{tail}} \exp(-\lambda_{\text{tail}} t). \quad (1)$$

The first term on the RHS represents the precession of muons stopped at the most probable sites [28]. The choice of a Bessel function, typically used to describe incommensurate structures [30] is in our case purely empirical. Nevertheless, its use is justified by preliminary neutron diffraction evidence [34] that the magnetic structure is actually helimagnetic in the b direction, perpendicular to the chains. Its exponential envelope reflects a narrow Lorentzian distribution of local fields and also takes into account the depolarization by nuclear spins. The characteristic muon spin precession frequency ω is directly proportional to the magnitude of the static magnetic field $\omega = \gamma B$, with $\gamma = 85.16 \text{ krad s}^{-1} \text{ G}^{-1}$, is thus our primary measure of the static magnetic order.

The second term in Eq. 1 empirically describes the multitude of other stopping sites sensitive to the static magnetic order. For each sample, the site occupancies

A_1 and A_2 , as well as parameters for “fast” and “tail” contributions, were determined in global fits to the data collected in the entire temperature range. The parameter ϕ determines the functional shape of the oscillatory term. At each temperature, it was globally applied to all samples, separately on the Br-rich and Cl-rich ends, to allow a direct comparison of the precession frequencies ω within each family of materials. For each sample, the parameters ω , λ_1 and λ_2 were refined at each temperature separately. The model provides excellent fits to all data collected for the ordered state in all samples. Typical fits are shown in heavy solid lines in Fig. 3. The values of all fit parameters for all samples and their temperature dependencies are deposited as supplementary material.

The main result of our analysis is the temperature dependence of the order parameter B , plotted in Fig. 4. For each composition, the temperature axis has been normalized to the value of T_c derived from calorimetric measurements. Three conclusions can be immediately drawn. First, in apparent contradiction with chain-MF theory, both T_N and the saturation magnetization m_0 are *reduced* in disordered samples, on both composition ends. Second, the Br-rich materials, which are more one-dimensional in nature, are considerably more affected by disorder than the more 3-dimensional Cl-rich systems. In $\text{Cu}(\text{py})_2(\text{Br}_{1-y}\text{Cl}_y)_2$, the oscillatory term is dramatically slowed already at 5% substitution, and is almost completely overrun by relaxation effects at 10% Cl. Third, for Br-rich samples the effect of bond disorder on m_0 is much more drastic than on T_N . This is made particularly clear by the m_0 vs. composition plot in Fig. 2. It is based on our initial estimates for m_0 in the disorder-free materials, and on the assumption that within each of the two series of materials m_0 is proportional to the Larmor field B extrapolated to zero temperature. Note that for $T \rightarrow 0$ the ratio of observed fields for the two disorder-free samples is actually very close to the ratio of estimated ordered moments, so the data in Fig. 4 can in practice be compared across all compositions.

Before we discuss these results, a few words need to be said on the nature of the bond disorder. That disorder effects are not apparent in bulk properties above T_N is not at all surprising. Recent numerical simulations and experimental studies of the RS material $\text{BaCu}_2\text{SiGeO}_7$ [32] have illustrated that the effect of even very large randomness of exchange constants may be very modest, as far as bulk properties are concerned. In fact, deviant behavior of susceptibility and magnetization curves may emerge only at temperature and field scales that are over an order of magnitude smaller than the width of the random bond distribution. Even if we assume that in $\text{Cu}(\text{py})_2(\text{Br}_{1-y}\text{Cl}_y)_2$ we are dealing with an extreme and clearly exaggerated bimodal distribution of exchange constants, a 10% substitution will produce a standard deviation of only about 0.7 meV. In this conservative estimate, RS behavior may be expected to affect the bulk

properties only at temperatures well below ~ 0.5 K, where we will have already entered the ordered phase. Here it should also be noted that the effect of chemical disorder on *inter-chain* interactions will have a minimal effect on 3D ordering. It will be averaged out by the very large correlation length in individual chains at low temperatures.

The effects of disorder and the drastic suppression of m_0 relative to T_N are most prominent in the Br-rich materials, which are more one-dimensional. Here the RS-related physics is more likely to play a role. RS properties emerge only below a certain energy scale that is non-universal and depends on the initial distribution of exchange constants [3–6]. In contrast to $\text{Cu}(\text{py})_2(\text{Br}_{1-y}\text{Cl}_y)_2$, in $\text{Cu}(\text{py})_2(\text{Cl}_{1-x}\text{Br}_x)_2$ this energy scale may be much lower than J' , making the disorder irrelevant in the ordered phase. The discrepancy between our findings and the chain-MF theory of Ref. [1] remains to be explained. One tantalizing possibility is that the chain-MF approach may be in principle be inapplicable to the RS phase [35]. The latter features an abundance of weakly-dimerized spin degrees of freedom for which quantum correlations with similar objects in adjacent chains simply can not be ignored.

A final note concerns the *homogeneity* of the static ordered moment. The low energy physics of the RS phase is *exactly* that of non-interacting random dimers with a universal probability distribution of dimer strength. These singlets will be partially polarized by the mean exchange field. The degree of polarization will be determined by the strength of the dimers. As a result, we expect a universal probability and spatial *distribution* of static ordered moments $P(m)$ in the $T \rightarrow 0$ limit. Even though muon spectroscopy could, in principle, measure this distribution directly, in $\text{Cu}(\text{py})_2(\text{Cl}_{1-x}\text{Br}_x)_2$ and $\text{Cu}(\text{py})_2(\text{Br}_{1-y}\text{Cl}_y)_2$ such an experiment appears very challenging. We believe that this elegant idea of a *universal distribution of ordered moments in weakly coupled RS chains* deserves more theoretical and experimental attention, using new materials for μ -SR and using alternative techniques such as NMR.
